# Operators in python

int213

## The modulus operator

- The modulus operator works on integers (and integer expressions) and yields the remainder when the first operand is divided by the second.
- In Python, the modulus operator is a percent sign (%).

## Example

• The syntax is the same as for other operators:

```
>>> quotient = 7 / /3
>>> print (quotient)
2
>>> remainder = 7 % 3
>>> print (remainder)
1
```

So 7 divided by 3 is 2 with 1 left over.

#### Uses

- Check whether one number is divisible by another if x % y is zero, then x is divisible by y.
- you can extract the right-most digit or digits from a number.
- For example,
- x % 10 yields the right-most digit of x (in base 10). Similarly x % 100 yields the last two digits.

## Boolean expressions

- A Boolean expression is an expression that is either true or false.
- One way to write a Boolean expression is to use the operator ==, which compares two values and produces a Boolean value:

True and False are special values that are built into Python.

#### **Comparison Operators**

```
• x != y
        # x is not equal to y
                                                                                   #
• x > y
  x is greater than y
                                                                                   #
x < y</li>x is less than y
• x >= y
       # x is greater than or equal to y
• x <= y
       "# x is less than or equal to y
NOTE: "= is an assignment operator and == is a comparison operator". Also,
there is no such thing as =< or =>.
```

#### Logical operators

There are three logical operators:

- and,
- or
- not
- For example, x > 0 and x < 10 is true only if x is greater than 0 and less than 10.
- n%2 == 0 or n%3 == 0
- not(x > y) is true if (x > y) is false, that is, if x is less than or equal to y.

## Identity operators

• Identity operators compare the memory locations of two objects. There are two Identity operators as explained below

| Operator | Description   | Example   |
|----------|---|---|
| is       | Evaluates to true if the variables on either side of the operator point to the same object and false otherwise. | x is y, here is results in 1 if id(x) equals id(y).                     |
| is not   | Evaluates to false if the variables on either side of the operator point to the same object and true otherwise. | x is not y, here is not results in<br>1 if id(x) is not equal to id(y). |

**Bitwise Operators** 

| Operator                       | Description  | Example  |
|--------------------------------|--|--|
| & Binary<br>AND                | Operator copies a bit to the result if it exists in both operands                            | (a & b) (means 0000 1100)  |
| Binary OR                      | It copies a bit if it exists in either operand.  | (a   b) = 61 (means 0011<br>1101)  |
| ^ Binary<br>XOR                | It copies the bit if it is set in one operand but not both.                                  | (a ^ b) = 49 (means 0011 0001)   |
| ~ Binary<br>Ones<br>Complement | It is unary and has the effect of 'flipping' bits.   | (~a) = -61 (means 1100<br>0011 in 2's complement<br>form due to a signed binary<br>number. |
| << Binary<br>Left Shift        | The left operands value is moved left by the number of bits specified by the right operand.  | a << = 240 (means 1111 0000)   |
| >> Binary<br>Right Shift       | The left operands value is moved right by the number of bits specified by the right operand. | a >> = 15 (means 0000<br>1111)   |

# **Membership Operators**

| Operator | Description  | Example  |
|----------|--|--|
| in       | Evaluates to true if it finds a variable in the specified sequence and false otherwise.          | x in y, here in results in a 1 if x is a member of sequence y.             |
| not in   | Evaluates to true if it does not finds a variable in the specified sequence and false otherwise. | x not in y, here not in results in a 1 if x is not a member of sequence y. |

#### Continue...

• Any nonzero number is interpreted as "true."

```
>>> x = 5
>>> x and 1
1
>>> y = 0
>>> y and 1
0
```

#### Keyboard Input

- input(): built in function to get data from keyboard.
- Takes data in the form of string.

```
Eg:
>>> input1 = input ()
What are you waiting for?
>>> print (input1)
What are you waiting for?
```

- Before calling input, it is a good idea to print a message telling the user what to input. This message is called a prompt.
- A prompt can be supplied as an argument to input.

```
    Eg:
        >>> name = input ("What...is your name? ")
        What...is your name? Arthur, King of the Britons!
        >>> print(name)
        Arthur, King of the Britons!
```

- If we expect the response to be an integer, then type conversion needs to be done.
- Eg:
   prompt = "What is the airspeed velocity of an unladen swallow?"
   speed =int(input(prompt))
